We present a search for the radiative leptonic decay $B^+ \rightarrow \ell^+ \nu_\ell \gamma$, where $\ell = e, \mu$, using a data sample of 465×10^6 $B\bar{B}$ pairs collected by the BABAR experiment. In this analysis, we fully reconstruct the hadronic decay of one of the B mesons in $\Upsilon(4S) \rightarrow B^+ B^-$ decays, then search for evidence of $B^+ \rightarrow \ell^+ \nu_\ell \gamma$ in the rest of the event. We observe no significant evidence of signal decays and report model-independent branching fraction upper limits of $\mathcal{B}(B^+ \rightarrow e^+ \nu_e \gamma) < 17 \times 10^{-6}$, $\mathcal{B}(B^+ \rightarrow \mu^+ \nu_\mu \gamma) < 24 \times 10^{-6}$, and $\mathcal{B}(B^+ \rightarrow \ell^+ \nu_\ell \gamma) < 15.6 \times 10^{-6}$ ($\ell = e$ or μ), all at the 90% confidence level.

The leptonic decay $B^+ \rightarrow \ell^+ \nu_\ell \gamma$ [1], where $\ell = e$ or μ , proceeds via quark annihilation into a virtual W^+ boson with the radiation of a photon. The presence of the photon removes the helicity suppression of the purely leptonic decays, $B^+ \rightarrow \ell^+ \nu_\ell$, although it introduces an additional suppression by a factor of α_{em} . The branching fraction of $B^+ \rightarrow \ell^+ \nu_\ell \gamma$ is predicted to be of order 10^{-6} [2], making it potentially accessible at B factories. The most stringent published limits are from the CLEO Collaboration with $\mathcal{B}(B^+ \rightarrow e^+ \nu_e \gamma) < 2.0 \times 10^{-4}$ and $\mathcal{B}(B^+ \rightarrow \mu^+ \nu_\mu \gamma) < 5.2 \times 10^{-5}$ at the 90% confidence level (C.L.) [3].

The differential branching fraction versus photon energy E_γ involves two form factors, f_V and f_A , which contain the long-distance contribution of the vector and axial currents, respectively, in the $B \rightarrow \gamma$ transition

$$\frac{d\mathcal{B}}{dE_\gamma} = \frac{\alpha_{\text{em}} G_F^2 |V_{ub}|^2}{48\pi^2} m_B^4 \tau_B [f_A^2(E_\gamma) + f_V^2(E_\gamma)] (1-y)y^3, \quad (1)$$

where G_F is the Fermi constant, V_{ub} is the Cabibbo-Kobayashi-Maskawa quark-mixing matrix element describing the coupling of b and u quarks, m_B and τ_B are the B -meson mass and lifetime, respectively, and $y \equiv 2E_\gamma/m_B$. While $f_A = f_V$ in most models [4], some suggest $f_A = 0$ [5]. The branching fraction is given by Ref. [6] as

$$\mathcal{B}(B^+ \rightarrow \ell^+ \nu_\ell \gamma) = \frac{\alpha_{\text{em}} G_F^2 |V_{ub}|^2}{288\pi^2} f_B^2 m_B^5 \tau_B \left(\frac{Q_u}{\lambda_B} - \frac{Q_b}{m_b} \right)^2, \quad (2)$$

where f_B is the B -meson decay constant, $Q_{u,b}$ are the u - and b -quark charges, and m_b is the b -quark mass. The first inverse moment of the B -meson distribution amplitude λ_B is expected to be of order Λ_{QCD} but its theoretical estimation suffers from large uncertainties [7]. It also appears in the branching fractions of two-body hadronic B -meson decays, such as $B \rightarrow \pi\pi$, and plays an important role in QCD factorization [4]. Since there are no hadrons in the final state, an experimental measurement of $B^+ \rightarrow \ell^+ \nu_\ell \gamma$ can provide a clean determination of λ_B .

We present the first search for $B^+ \rightarrow \ell^+ \nu_\ell \gamma$ that exploits the hadronic “recoil” technique, in which one B meson is exclusively reconstructed in a hadronic final state before searching for the signal decay within the rest of the event. This technique improves the handling of event kinematics, providing adequate background suppression without requiring model-dependent constraints on the signal kinematics. Thus, this analysis is valid for all $B \rightarrow \gamma$ form-factor models and over the full kinematic range. This analysis uses a data sample of 465 ± 5 million $B\bar{B}$ pairs, corresponding to an integrated luminosity of 423 fb^{-1} collected at the $\Upsilon(4S)$ resonance. The data were recorded with the BABAR detector at the asymmetric-energy PEP-II e^+e^- storage ring at SLAC. The BABAR detector is described in detail elsewhere [8].

Signal and background decays are studied using Monte Carlo (MC) samples based on GEANT4 [9]. The simulation includes a detailed model of the BABAR detector geometry and response. Beam-related background and detector noise are extracted from data and overlaid on the MC simulations. $\Upsilon(4S) \rightarrow B\bar{B}$ signal MC samples are generated with one B meson decaying via $B^+ \rightarrow \ell^+ \nu_\ell \gamma$ using the tree-level model of Ref. [6], which is valid for $y > 0.13$, while the other B meson decays generically. We simulate signal MC samples for two form-factor models, with $f_A = f_V$ and $f_A = 0$ respectively, to evaluate the impact of the decay model on the signal selection efficiency. Large MC samples of generic $B\bar{B}$ and continuum ($e^+e^- \rightarrow \tau^+\tau^-$ or $e^+e^- \rightarrow q\bar{q}$, where $q = u, d, s, c$) events are used to optimize the signal selection criteria. However, the final background estimates are obtained directly from a combination of data and exclusive $B^+ \rightarrow X_u^0 \ell^+ \nu_\ell$ MC samples, where X_u^0 is a neutral meson containing a u quark. The primary background for $B^+ \rightarrow \ell^+ \nu_\ell \gamma$ in this analysis is due to $B^+ \rightarrow X_u^0 \ell^+ \nu_\ell$ decays, with $B^+ \rightarrow \pi^0 \ell^+ \nu_\ell$ ($B^+ \rightarrow \eta \ell^+ \nu_\ell$) comprising approximately 73% (18%) of this semileptonic background. The branching fraction and uncertainty for each $B^+ \rightarrow X_u^0 \ell^+ \nu_\ell$ mode are taken from experimental measurements ($X_u^0 = \pi^0$ [10], ρ [10], η [11], and ω [12]). We assume $\mathcal{B}(B^+ \rightarrow \eta' \ell^+ \nu_\ell) = \mathcal{B}(B^+ \rightarrow \eta \ell^+ \nu_\ell) \times (1 \pm 1)$. We use a light-cone sum rule model for the η and η' form factors [13] and use the form factor measured in a BABAR analysis [14] with the shape parameterization given in Ref. [15] for the π^0 mode.

Event selection begins with the full reconstruction of a charged B meson (B_{tag}) in one of the large number of hadronic final states, $B^- \rightarrow \bar{D}^{(*)} X_{\text{had}}$. We reconstruct the $D^{*-} \rightarrow \bar{D}^0 \pi^-$; $\bar{D}^{*0} \rightarrow \bar{D}^0 \pi^0$, $\bar{D}^0 \gamma$; $D^- \rightarrow K_s^0 \pi^-$, $K_s^0 \pi^- \pi^0$, $K_s^0 \pi^- \pi^- \pi^+$, $K^+ \pi^- \pi^-$, $K^+ \pi^- \pi^- \pi^0$; $\bar{D}^0 \rightarrow K^+ \pi^-$, $K^+ \pi^- \pi^0$, $K^+ \pi^- \pi^- \pi^+$, $K_s^0 \pi^- \pi^+$; and $K_s^0 \rightarrow \pi^- \pi^+$ decay modes. X_{had} is a collection of at most five mesons, composed of both charged and neutral kaons and pions. Well-reconstructed B_{tag} candidates are selected using two kinematic variables: $\Delta E = E_{B_{\text{tag}}} - \sqrt{s}/2$ and $m_{\text{ES}} = \sqrt{s/4 - \vec{p}_{B_{\text{tag}}}^2}$, where $E_{B_{\text{tag}}}$ and $\vec{p}_{B_{\text{tag}}}$ are the energy and momentum of the B_{tag} candidate, respectively, and \sqrt{s} is the total energy of the e^+e^- system, all in the center-of-mass (CM) frame. We require ΔE , which peaks at zero for correctly reconstructed B mesons, to lie between -0.12 and 0.12 GeV or within two standard-deviations from its mean for the given X_{had} mode, whichever is the tighter constraint. We fit the m_{ES} distribution for each X_{had} mode and require that the purity, or fraction of well-reconstructed B mesons, is greater than 12% in the region $m_{\text{ES}} > 5.27 \text{ GeV}/c^2$. If more than one B_{tag} candidate is reconstructed, the one in the highest purity mode is chosen. If there are multiple candidates in this mode, the one that minimizes $|\Delta E|$ is selected.

FIG. 1: m_{ES} distribution, after B_{tag} reconstruction and continuum suppression, of data (points) and the expected combinatoric background as predicted by the MC (shaded).

We define the signal region as $5.27 < m_{ES} < 5.29$ GeV/c^2 , since correctly reconstructed B mesons peak in this region near the nominal B -meson mass. The B_{tag} candidates that are incorrectly reconstructed from either continuum events or both B mesons (“combinatoric” events), produce a distribution that is fairly flat below the m_{ES} signal region and decreases within it, as shown in Fig. 1. The shape of the combinatoric distribution is extrapolated into the m_{ES} signal region using MC, while the background contribution from combinatoric events is estimated directly from the data. To improve the MC estimate of the B_{tag} reconstruction efficiency, we normalize the generic MC to the number of data events that peak within the m_{ES} signal region. Thus, all MC samples are scaled by 90.7%, resulting in good agreement between data and background MC throughout the analysis selection. A charged B_{tag} is reconstructed in about 0.3% of the signal MC events.

Because the two B mesons produced in the $\Upsilon(4S)$ decay have low momenta in the CM frame (0.3 GeV/c), their decay products are more isotropic than continuum background. For example, $|\cos\theta_T|$, where θ_T is the angle in the CM frame between the B_{tag} thrust axis and the thrust axis of all other particles in the event, has a flat distribution for $B\bar{B}$ events and peaks near one for non- $B\bar{B}$ events. The continuum background is suppressed by requiring $\mathcal{L}_B \equiv \prod_i \mathcal{P}_B(x_i) / (\prod_i \mathcal{P}_B(x_i) + \prod_i \mathcal{P}_q(x_i)) > 30\%$, where $\mathcal{P}_B(x_i)$ ($\mathcal{P}_q(x_i)$) are probability density functions determined from MC that describe $B\bar{B}$ (continuum) events for the five event-shape variables x_i . The variables used are: the ratio of the second to zeroth Fox-Wolfram moment [16] computed using all charged and neutral particles in the event, the cosine of the angle between $\vec{p}_{B_{tag}}$ and the beam axis, the magnitude of the B_{tag} thrust, the component of the B_{tag} thrust along the beam axis, and $|\cos\theta_T|$. This requirement improves the agreement between data and MC by suppressing unmodeled continuum backgrounds, such as $e^+e^- \rightarrow e^+e^-\ell^+\ell^-$ via two photons.

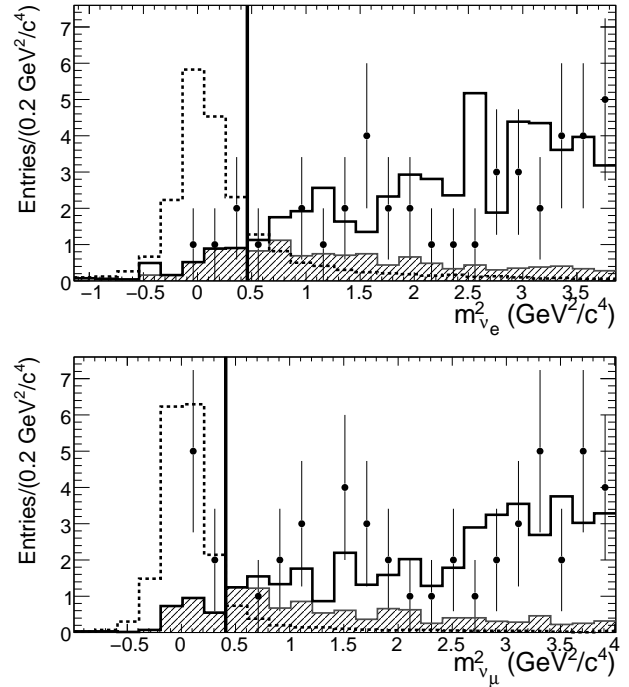

FIG. 2: m_{ν}^2 distribution after all selection criteria are applied, in electron (top) and muon (bottom) modes for the m_{ES} -peaking (shaded) plus nonpeaking (solid) contributions in the full background MC sample, signal MC normalized to $\mathcal{B} = 40 \times 10^{-6}$ (dashed), and data (points). Events to the left of the vertical lines are selected. N_{ℓ}^{comb} of Table I is determined from sideband data, not from the MC shown here.

In the sample of selected B_{tag} candidates, we identify events in which the remaining tracks, calorimeter clusters, and missing momentum vector (\vec{p}_{miss}) are consistent with $B^+ \rightarrow \ell^+ \nu_{\ell} \gamma$ candidates. We select events with exactly one track, which reduces the signal efficiency by 25% but removes over 99% of the simulated background events with a reconstructed B_{tag} . This signal track is required to have a charge opposite to that of the B_{tag} , to satisfy particle identification (PID) criteria for either a muon or electron, and to be inconsistent with a kaon hypothesis. In the electron mode, the four-momenta of signal tracks are redefined to include those of any bremsstrahlung photon candidates. Such a candidate is defined as any cluster whose momentum vector, when compared to that of the signal track (\vec{p}_{ℓ}), is separated by $|\Delta\theta| < 3^\circ$ and $-3^\circ < Q_e \times \Delta\phi < 13^\circ$, where $Q_e = \pm 1$ is the e^\pm charge and θ (ϕ) is the polar (azimuthal) angle relative to the beam axis, in the lab frame. Finally, the signal photon candidate is chosen as the cluster with the highest CM energy, excepting bremsstrahlung photon candidates.

We significantly reduce the background by requiring that the kinematics of the signal track and photon candidate are consistent with the existence of a third mass-

less particle originating from the signal B meson. To do this, we use the four-momentum of the expected signal B meson (p_B), which is assigned an energy of $\sqrt{s}/2$, a momentum vector pointing along $-\vec{p}_{B_{\text{tag}}}$, and the nominal B -meson mass. The neutrino mass squared is then defined as $m_\nu^2 \equiv (p_B - p_\ell - p_\gamma)^2$, where p_ℓ (p_γ) is the four-momentum of the signal track (photon candidate). As shown in Fig. 2, the background increases with m_ν^2 , while $B^+ \rightarrow \ell^+ \nu_\ell \gamma$ events peak at $m_\nu^2 = 0$ with an enhanced tail in the electron mode due to unrecovered bremsstrahlung photons. We require $-1 < m_\nu^2 < 0.46$ (0.41) GeV^2/c^4 for the electron (muon) modes. In addition, the lepton and neutrino should be emitted back-to-back in the rest frame that recoils from the photon emission, defined as $p_B - p_\gamma$. We require $\cos \theta_{\ell\nu} < -0.93$ in this frame, where $\theta_{\ell\nu}$ is the angle between \vec{p}_ℓ and \vec{p}_{miss} . After all other selection criteria are applied, the MC indicates that m_ν^2 and $\cos \theta_{\ell\nu}$ together remove 99% of background events with a 30 and 20% reduction in the signal efficiency for the electron and muon modes, respectively.

The dominant backgrounds are due to $B^+ \rightarrow \pi^0 \ell^+ \nu_\ell$ ($\eta \ell^+ \nu_\ell$) events in which $\pi^0(\eta) \rightarrow \gamma\gamma$ fakes the $B^+ \rightarrow \ell^+ \nu_\ell \gamma$ signal photon. To suppress this background, we reject events containing a $\pi^0(\eta)$ candidate, reconstructed using the signal photon candidate and a second cluster having CM energy E_{γ_2} . For π^0 candidates, we require a $\gamma\gamma$ invariant mass between 120–145 MeV/c^2 with $E_{\gamma_2} > 30$ MeV or between 100–160 MeV/c^2 with $E_{\gamma_2} > 80$ MeV . For η candidates, we require a $\gamma\gamma$ invariant mass between 515–570 MeV/c^2 with $E_{\gamma_2} > 100$ MeV . Likewise, $B^+ \rightarrow \omega \ell^+ \nu_\ell \rightarrow [\pi^0 \gamma] \ell^+ \nu_\ell$ events are suppressed by rejecting any event in which the signal photon candidate and a π^0 candidate produce an invariant mass between 730–830 MeV/c^2 . This π^0 candidate is defined as any two clusters with CM energy > 70 MeV which produce a $\gamma\gamma$ invariant mass between 115–145 MeV/c^2 . After applying all other selection criteria, these vetoes reduce the $B^+ \rightarrow \pi^0 \ell^+ \nu_\ell$ and $B^+ \rightarrow X_u^0 \ell^+ \nu_\ell$ background events, with $X_u^0 \neq \pi^0$, by 65% and 50% respectively. Finally, we require the lateral moment [17] of the calorimeter energy deposit for the signal photon candidate, which peaks at 25% for single photons, to be between 0 and 55%. This suppresses $B^+ \rightarrow \pi^0 \ell^+ \nu_\ell$ events in which the two photons from the π^0 decay are reconstructed as a single merged photon.

Once the B_{tag} , signal photon, and lepton are identified, $B^+ \rightarrow \ell^+ \nu_\ell \gamma$ events are expected to contain little or no additional energy within the calorimeter. However, additional energy deposits can result from hadronic shower fragments, beam-related photons, and photons from unreconstructed $\bar{D}^* \rightarrow \bar{D}\gamma/\pi^0$ transitions in the B_{tag} candidate. The total energy of all additional clusters is required to be less than 0.8 GeV , counting only clusters with lab-frame energy greater than 50 MeV . We also require that \vec{p}_{miss} points within the fiducial acceptance of the detector.

To avoid experimenter bias, we optimize all the se-

FIG. 3: m_ν^2 distribution for $B^+ \rightarrow \pi^0 \ell^+ \nu_\ell$ ($\ell = e$ and μ), using the procedure described in the text where γ is substituted with a π^0 candidate, of data (points) and of $B^+ \rightarrow \pi^0 \ell^+ \nu_\ell$ MC normalized to $\mathcal{B} = 7.7 \times 10^{-5}$ (dashed) and added to the expected background (solid).

lection criteria and determine the number of expected background events in the signal region (N_ℓ^{bkg}), for $\ell = e$ or μ , before looking at any data events selected by the criteria. We optimize by maximizing the figure of merit $\varepsilon_\ell^{\text{sig}} / (\frac{1}{2}n_\sigma + \sqrt{N_\ell^{\text{bkg}}})$ [18], where $n_\sigma = 1.3$ and $\varepsilon_\ell^{\text{sig}}$ is the total signal efficiency including that of the B_{tag} reconstruction. The signal branching fraction is calculated using $\mathcal{B}_\ell = (N_\ell^{\text{obs}} - N_\ell^{\text{bkg}}) / \varepsilon_\ell^{\text{sig}} N_{B^\pm}$, where $N_{B^\pm} = 465 \times 10^6$ is the number of B^\pm mesons in the data sample and N_ℓ^{obs} is the number of data events within the signal region.

To verify the modeling of $\varepsilon_\ell^{\text{sig}}$, we remove the $B^+ \rightarrow X_u^0 \ell^+ \nu_\ell$ vetoes, select events containing a π^0 candidate, and substitute the π^0 in place of the signal photon candidate. The resulting m_ν^2 distribution from $B^+ \rightarrow \pi^0 \ell^+ \nu_\ell$ is expected to resemble that of the signal. We observe a peak in the data that agrees with MC expectations within the 15% statistical uncertainty of the data, as shown in Fig. 3. For cross-check purposes only, we determine the $B^+ \rightarrow \pi^0 \ell^+ \nu_\ell$ efficiency using an exclusive $B^+ \rightarrow \pi^0 \ell^+ \nu_\ell$ MC sample and the background contribution using generic MC. The peak in data corresponds to $\mathcal{B}(B^+ \rightarrow \pi^0 \ell^+ \nu_\ell) = (7.8_{-1.1}^{+1.7}) \times 10^{-5}$, where the uncertainty is statistical. This branching fraction is consistent with the current world-average value of $(7.7 \pm 1.2) \times 10^{-5}$ [10], which is also the value used in the MC samples.

The total number of background events N_ℓ^{bkg} has two components: N_ℓ^{peak} the number of expected background events having a correctly reconstructed B_{tag} and hence peaking within the m_{ES} signal region, and N_ℓ^{comb} the number of expected combinatoric background events, including both $B\bar{B}$ and continuum events. The m_ν^2 and $\cos \theta_{\ell\nu}$ restrictions ensure kinematic and topological consistency with a three-body decay involving a massless and undetected particle: the neutrino. By further requiring that exactly one track recoils from a fully-reconstructed B_{tag} , lepton number and PID ensures the track is a lepton. Thus, only $B^+ \rightarrow \ell^+ \nu_\ell \gamma$ decays can peak within

the signal region, unless the signal photon candidate actually arises from one or more particles that mimic the kinematics of $B^+ \rightarrow \ell^+ \nu_\ell \gamma$, which only occurs in specific pathological $B^+ \rightarrow X_u^0 \ell^+ \nu_\ell$ decays. Therefore, we determine N_ℓ^{peak} using exclusive $B^+ \rightarrow X_u^0 \ell^+ \nu_\ell$ MC simulations and validate the lack of additional peaking backgrounds with generic MC. Other decay modes passing the selection criteria do so with poorly reconstructed B_{tag} candidates and thus produce a combinatoric distribution in m_{ES} . We determine N_ℓ^{comb} from an extrapolation of the observed number of data events within the m_{ES} sideband region, defined as $5.20 < m_{\text{ES}} < 5.26 \text{ GeV}/c^2$. We observe 1 (4) data events within the m_{ES} sideband for the electron (muon) mode.

The uncertainty on N_ℓ^{comb} is dominated by the sideband data statistics. It also includes the systematic uncertainty from the combinatoric background shape, estimated by varying the selection criteria and the method used to extrapolate this shape (14.6%). The error on N_ℓ^{peak} is dominated by uncertainties in the branching fractions and form factors associated with the various exclusive $B^+ \rightarrow X_u^0 \ell^+ \nu_\ell$ decays (13.6%). Additional systematic uncertainties result from MC modeling of the data efficiency, which we apply to both N_ℓ^{peak} and $\varepsilon_\ell^{\text{sig}}$: electron PID (0.9%) or muon PID (1.3%), \mathcal{L}_B (1.4%), m_ν^2 (0.5% for $\varepsilon_\ell^{\text{sig}}$, 1.4% for N_ℓ^{peak}), and the reconstructions of the track (0.4%), photon (1.8%), and B_{tag} (3.1%). The last of these, which also accounts for uncertainty in N_{B^\pm} , is estimated by varying the shape of the m_{ES} combinatoric distribution and the size of the m_{ES} signal and sideband regions.

Branching fraction limits and uncertainties are computed using the frequentist formalism of Feldman and Cousins [19], with the uncertainties on N_ℓ^{bkg} and $\varepsilon_\ell^{\text{sig}}$ modeled using Gaussian distributions. Since $\mathcal{B}(B^+ \rightarrow \ell^+ \nu_\ell \gamma)$ is expected to be independent of the lepton type, we also combine the two modes by maximizing a likelihood function defined as the product of both Poisson probabilities in N_ℓ^{bkg} , where \mathcal{B}_ℓ is the mean.

We observe 4 (7) data events within the signal region for the electron (muon) mode, compared to an expected background of 2.7 ± 0.6 (3.4 ± 0.9) events. This corresponds to a signal significance of 1.2σ (1.8σ), a combined significance of 2.1σ , and the results given in Table I. The effective detector and PID thresholds are about 20 MeV for photon energy and 400 (800) MeV/ c for electron (muon) momentum, and we apply no minimum energy requirements. Thus, this analysis is essentially independent of the kinematic model; we assume the $f_A = f_V$ signal model, but the $f_A = 0$ model yields consistent $\varepsilon_\ell^{\text{sig}}$ values. Since certain theoretical calculations are most reliable at high E_γ [7], we also report a partial branching fraction limit $\Delta\mathcal{B}$ by selecting events with a photon candidate energy greater than 1 GeV, which reduces $\varepsilon_\ell^{\text{sig}}$ by 30%. We observe 2 (4) data

events with $N_\ell^{\text{bkg}} = 1.4 \pm 0.3$ (2.5 ± 1.0), resulting in $\Delta\mathcal{B}(B^+ \rightarrow \ell^+ \nu_\ell \gamma) < 14 \times 10^{-6}$ at 90% C.L.

In Table I, we also report model-specific limits by introducing a kinematic requirement on the relationship between $\cos \theta_{\gamma\ell}$ and $\cos \theta_{\gamma\nu}$, where $\theta_{\gamma\ell}$ ($\theta_{\gamma\nu}$) is the angle between the photon candidate momentum and \vec{p}_ℓ (\vec{p}_{miss}) in the signal B rest frame. The photon is emitted preferentially back-to-back with the lepton in the $f_A = f_V$ model, and with either the lepton or neutrino when $f_A = 0$. Thus, we require $(\cos \theta_{\gamma\ell} - 1)^2 + (\cos \theta_{\gamma\nu} + 1)^2/3 > 0.4$ or $(\cos \theta_{\gamma\nu} - 1)^2 + (\cos \theta_{\gamma\ell} + 1)^2/3 > 0.4$ for the $f_A = 0$ model, and only the former relationship for $f_A = f_V$. This reduces $\varepsilon_\ell^{\text{sig}}$ in both modes and models by 40%. We observe 0 (0) data events in the electron (muon) mode with $N_\ell^{\text{bkg}} = 0.6 \pm 0.1$ (1.0 ± 0.4) for the $f_A = f_V$ model, and 3 (2) data events with $N_\ell^{\text{bkg}} = 1.2 \pm 0.4$ (1.5 ± 0.6) for $f_A = 0$.

In conclusion, we have searched for $B^+ \rightarrow \ell^+ \nu_\ell \gamma$ using a hadronic recoil technique and observe no significant signal within a data sample of 465×10^6 $B\bar{B}$ pairs. We present model-specific branching fraction limits in Table I. We also report a model-independent limit of $\mathcal{B}(B^+ \rightarrow \ell^+ \nu_\ell \gamma) < 15.6 \times 10^{-6}$ at the 90% C.L., which is consistent with the standard model prediction and is the most stringent published upper limit to date. Using Eq.(2) with $f_B = 0.216 \pm 0.022 \text{ GeV}$ [20], $m_B = 5.279 \text{ GeV}/c^2$, $\tau_B = 1.638 \text{ ps}$, $m_b = 4.20 \text{ GeV}/c^2$, and $|V_{ub}| = (3.93 \pm 0.36) \times 10^{-3}$ [10], the combined branching fraction likelihood function corresponds to a limit of $\lambda_B > 0.3 \text{ GeV}$ at the 90% C.L.

We are grateful for the excellent luminosity and machine conditions provided by our PEP-II colleagues, and for the substantial dedicated effort from the computing organizations that support BABAR. The collaborating institutions wish to thank SLAC for its support and kind hospitality.
